

11B Made in the Neutrino Process Constrains the Neutrino Spectra from Core Collapse Supernovae

Schematic of the neutrino process. The proto neutron star formed in a core collapse supernova emits neutrinos which dissociate ${}^{12}\text{C}$ leading to ${}^{11}\text{C}$ and ${}^{11}\text{B}$. After processing in the hot environment and the decay of ${}^{11}\text{C}$, some ${}^{11}\text{B}$ will be returned to the interstellar medium.

Production of ${}^{11}\text{B}$ by the neutrino process for various values of the triple alpha rate. A production factor (PF) of 0.42 means that the solar system abundance of ${}^{11}\text{B}$ is reproduced.

We have used KEPLER calculations to estimate the production of the light elements ${}^7\text{Li}$, ${}^{11}\text{B}$, and ${}^{19}\text{F}$ in supernova explosions. We find that they are produced in the neutrino process outlined above. The results are shown as production factors (PF), the ratios of the SN production to the observed abundance. Straightforward arguments indicate that about 42% of ${}^{11}\text{B}$ is made by the neutrino process, the rest by the galactic cosmic rays (GCR). Thus a production factor of 0.42 would, in combination with the GCR, reproduce the observed abundance.

We see that the neutrino process production of ${}^{11}\text{B}$ is a factor of 2-3 larger than observed. This may mean that SN produce fewer neutrinos than we have assumed (3×10^{53} ergs) or that the neutrinos are less energetic than assumed (4-6 MeV Fermi-Dirac distributions). Or that the nuclear processes involved in processes are not well enough understood. These processes must be further studied to improve the constraints.
